

9. Measurements of time series

Contents

1. Revisiting mean and variance
 2. Autocorrelation and independence
 3. Sample statistics
-

(All variables are real and one-dimensional unless otherwise specified.)

Suppose we have obtained a time series that is guaranteed to become **stationary** after some time. As the properties of a stationary time series no longer changes with time, we can estimate its **population** mean and variance with their **sample** counterparts reasonably.

1. Revisiting mean and variance

As you have surely known, the mean μ and variance σ^2 of a continuous random variable X are fundamentally defined with its distribution $f(x)$.

$$\begin{aligned}\mu &\equiv \int x f(x) dx \\ \mu &\equiv \int x f(x) dx \\ \sigma^2 &\equiv \int (x - \mu)^2 f(x) dx \\ \sigma^2 &\equiv \int (x - \mu)^2 f(x) dx\end{aligned}$$

These are, precisely speaking, the **population mean** and **population variance** of X because they are constants and do not depend on any specific realizations. Note that

$$\begin{aligned}\sigma^2 &= \int (x - \mu)^2 f(x) dx \\ &= \underbrace{\int x^2 f(x) dx}_{\langle X^2 \rangle} - 2\mu \underbrace{\int x f(x) dx}_{\mu} + \mu^2 \underbrace{\int f(x) dx}_1 \\ &= \langle X^2 \rangle - \mu^2.\end{aligned}$$

$$\begin{aligned}
\sigma^2 &= \int (x - \mu)^2 f(x) dx \\
&= \int x^2 f(x) dx - 2\mu \int x f(x) dx + \mu^2 \int f(x) dx \\
&\quad \underbrace{\int x^2 f(x) dx}_{\langle X^2 \rangle} \quad \underbrace{2\mu \int x f(x) dx}_{2\mu} \quad \underbrace{\int f(x) dx}_1 \\
&= \langle X^2 \rangle - \mu^2.
\end{aligned}$$

The mean tells us the **expected value** of X , i.e. literally, the average value of X you expect to see after almost infinitely many trials, but the expected value itself may never be realized at all. (The expected value of a fair dice is 3.5, but you will never get this value with the dice.) The variance measures the **dispersion** of X around its mean, aka its **central tendency**.

However, we rarely know the distribution and thus the values of population mean and population variance, so we need to **estimate them with samples** instead. Given a set of realizations

$\{x_1, x_2, \dots, x_n\}$, the **sample mean** $\hat{\mu}$ of X is simply

$$\begin{aligned}
\hat{\mu} &= \frac{1}{n} \sum_{i=1}^n x_i, \\
\hat{\mu} &= \frac{1}{n} \sum_{i=1}^n x_i,
\end{aligned}$$

whereas its **sample variance** $\hat{\sigma}^2$ is defined as

$$\begin{aligned}
\hat{\sigma}^2 &= \frac{1}{n-1} \sum_{i=1}^n (x_i - \hat{\mu})^2 \equiv \frac{n}{n-1} (\overline{x^2} - \hat{\mu}^2) \\
\hat{\sigma}^2 &= \frac{1}{n-1} \sum_{i=1}^n (x_i - \hat{\mu})^2 \equiv \frac{n}{n-1} \left(\overline{x^2} - \hat{\mu}^2 \right)
\end{aligned}$$

for $\overline{x^2} \equiv \frac{1}{n} \sum_{i=1}^n x_i^2$. Although there are n terms in the summation of $\hat{\sigma}^2$, the

estimate is argued to be more accurate if $\frac{1}{n-1}$ is used as the leading factor instead of $\frac{1}{n}$. This is known as **Bessel's correction**.

1.1 Notations

The mentioned concepts may be denoted by different symbols in different contexts **inconsistently**.

- **Letters.** Population mean and population variance are commonly denoted by Greek letters μ and σ^2 . Their sample counterparts may be denoted by Roman letters m and s^2 instead.

- **Bar.** A bar $\bar{}$ is commonly put on a variable's sample mean, so \bar{x} may denote the mean of $\{x_1, x_2, \dots, x_n\}$, i.e. the sample mean of X .
- **Hat.** Statistics commonly puts a hat $\hat{}$ on an estimated value, so $\hat{\mu}$ may denote the estimated value of μ .
- **Angle brackets.** Physics commonly encloses a population mean (also called an **ensemble average** in physics) with angle brackets $\langle \rangle$, so $\langle X \rangle$ may denote the population mean of X .
- **Operators.** An explicit operator E may be used to emphasize that a population mean represents an expected value, so $E(X)$ may denote the population mean of X .

1.2 Central limit theorem

The sample mean $\hat{\mu}$ is used to estimate the population mean μ , so we would like to know how much $\hat{\mu}$ differs from μ . But before answering this, we need to understand that $\hat{\mu}$ is also a random variable since we obtain different samples means from different trials of the same experiment. The distribution of $\hat{\mu}$ may be called the **sampling distribution of mean**.

While each realization of $\hat{\mu}$ is calculated by averaging $\{x_1, x_2, \dots, x_n\}$, the **central limit theorem** states that as the **sample size** n approaches infinity, the sample distribution becomes a normal distribution with mean μ and variance $\frac{\sigma^2}{n}$, where μ and σ^2 are the population mean and population variance of X ,

$$\hat{\mu} \stackrel{n \rightarrow \infty}{\sim} \mathcal{N}\left(\mu, \frac{\sigma^2}{n}\right)$$

$$\hat{\mu} \stackrel{n \rightarrow \infty}{\sim} N\left(\mu, \frac{\sigma^2}{n}\right)$$

1.3 Standard error of mean

We can therefore quantify how much the sample mean $\hat{\mu}$ of a specific trial differs from the population mean μ by the **standard deviation** $\sqrt{\frac{\sigma^2}{n}}$ of the sampling distribution (given that n is large enough). But since we do not know the population variance σ^2 , we need to replace this standard deviation with another estimate

$$\delta = \sqrt{\frac{\hat{\sigma}^2}{n}},$$

$$\delta = \sqrt{\frac{\hat{\sigma}^2}{n}},$$

where $\hat{\sigma}^2$ is the sample variance of the trial. The value δ is called the **standard error of mean**.

Qualitatively, a small δ suggests a high accuracy in $\hat{\mu}$, so the accuracy increases as the sample size n grows. Quantitatively, **frequentist statistics** tells us that the probability that $\hat{\mu}$ covers μ follows the standard normal distribution, i.e.

$$P(\hat{\mu} - z\delta \leq \mu \leq \hat{\mu} + z\delta) = C(z) \equiv \frac{1}{\sqrt{2\pi}} \int_{-z}^z e^{-x^2/2} dx$$

$$P(\hat{\mu} - z\delta \leq \mu \leq \hat{\mu} + z\delta) = C(z) \equiv \frac{1}{\sqrt{2\pi}} \int_{-z}^z e^{-x^2/2} dx$$

for some $z > 0$. The range $[\hat{\mu} - z\delta, \hat{\mu} + z\delta]$ is called the $[100 C(z)]\%$ **confidence interval** of μ .

Interpretation. Frequentists argue that $[\hat{\mu} - z\delta, \hat{\mu} + z\delta]$ is a **variable range** because $\hat{\mu}$ and δ are random variables yet to be measured. Once they are determined to be $\hat{\mu}_{\{x\}}$ and $\delta_{\{x\}}$ by a particular set of realizations $\{x\}$, the range collapses into a **fixed range** $[\hat{\mu}_{\{x\}} - z\delta_{\{x\}}, \hat{\mu}_{\{x\}} + z\delta_{\{x\}}]$ and implies

$$P(\hat{\mu}_{\{x\}} - z\delta_{\{x\}} \leq \mu \leq \hat{\mu}_{\{x\}} + z\delta_{\{x\}}) \in \{0, 1\}$$

$$P(\hat{\mu}_{\{x\}} - z\delta_{\{x\}} \leq \mu \leq \hat{\mu}_{\{x\}} + z\delta_{\{x\}}) \in \{0, 1\}$$

because the population mean μ is a constant that certainly falls into or outside a fixed range. For example, given $z = 1.96 \Rightarrow C(z) \approx 0.95$ and thus 95% confidence intervals, frequentists never claim the proposition " $\mu \in [\hat{\mu}_{\{x\}} - 1.96 \delta_{\{x\}}, \hat{\mu}_{\{x\}} + 1.96 \delta_{\{x\}}]$ " is 95% true—it is either 100% true or 100% false—but they only claim that after repeating the experiment for many times, 95% of all the obtained ranges $\{[\hat{\mu}_{\{x\}} - 1.96 \delta_{\{x\}}, \hat{\mu}_{\{x\}} + 1.96 \delta_{\{x\}}]\}$ satisfy the proposition " $\mu \in [\hat{\mu} - 1.96 \delta, \hat{\mu} + 1.96 \delta]$ ".

Unfortunately, it is very common for scientists to use these frequentist concepts without following the frequentist interpretation.

Fig. 1. This picture summarizes the previous paragraphs. Retrieved from [Wikimedia Commons](https://upload.wikimedia.org/wikipedia/commons/5/5c/Normal_distribution_50%25_CI_illustration.svg) (https://upload.wikimedia.org/wikipedia/commons/5/5c/Normal_distribution_50%25_CI_illustration.svg).

- The bell curve shows the distribution of the sample mean $\hat{\mu}$, i.e. the sampling distribution of mean, of a random variable X . The sample means $\{\hat{\mu}\}$ are normally distributed around X 's population mean μ once they are calculated with a large sample size.
- 20 trials are performed to measure X . Each set of realizations $\{x\}$ (the black dots) yield a sample mean $\hat{\mu}_{\{x\}}$ (the red or blue dots) and a standard error $\delta_{\{x\}}$ and thus form a fixed range $\left[\hat{\mu}_{\{x\}} - z\delta_{\{x\}}, \hat{\mu}_{\{x\}} + z\delta_{\{x\}}\right]$ (the horizontal bars). Here, $C(z) = 0.5 \Rightarrow z = 0.67$ is used, so the ranges are 50% confidence intervals.
- Some of the fixed ranges can cover μ (the blue dots and bars), but some cannot (the red ones). Since they are 50% confidence intervals, 50% of the trials are expected to produce a range that can cover μ .

Now, X is no longer a random variable but a time series $X = \{X_t \mid 1 \leq t \leq T\}$

$X = \{X_t \mid 1 \leq t \leq T\}$, which is random but surely stationary after some time. When we are asked to calculate its sample mean $\hat{\mu}$ and sample variance $\hat{\sigma}^2$, we may be tempted to treat the values $\{X_1, X_2, \dots, X_T\}$ like the realizations $\{x_1, x_2, \dots, x_n\}$ of a random variable and thus claim

$$\hat{\mu} = \frac{1}{T} \sum_{i=1}^T X_i \quad \text{and} \quad \hat{\sigma}^2 = \frac{1}{T-1} \sum_{i=1}^T (X_i - \hat{\mu})^2.$$

$$\hat{\mu} = \frac{1}{T} \sum_{i=1}^T X_i \quad \text{and} \quad \hat{\sigma}^2 = \frac{1}{T-1} \sum_{i=1}^T (X_i - \hat{\mu})^2.$$

However, this approach is problematic because unlike $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\} \{x_1, x_2, \dots, x_n\}$, $\{\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_T\} \{X_1, X_2, \dots, X_T\}$ lack **statistical independence** and yield biased results.

2. Autocorrelation and independence

We can extract statistically independent data points from $\{\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_T\} \{X_1, X_2, \dots, X_T\}$ for the calculation by considering its **autocorrelation** A_A , which tells us how strongly $\mathbf{X}\mathbf{X}$ correlates with its previous self. As we learnt previously, A_A is defined as

$$A_\lambda = \langle (\mathbf{X}_t - \boldsymbol{\mu}) (\mathbf{X}_{t+\lambda} - \boldsymbol{\mu}) \rangle$$

$$A_\lambda = \langle (X_t - \mu) (X_{t+\lambda} - \mu) \rangle$$

for some discrete lag $\lambda \geq 0$, where $\boldsymbol{\mu}$ is the population mean of $\mathbf{X}\mathbf{X}$ and the ultimate quantity that we are looking for. Doesn't this create a circular dependency?

2.1 Practical definitions

There are several ways to realize the formula in order to resolve the problem. Here are two possibilities:

$$A_\lambda^{(1)} = \left\langle \left(\mathbf{X}_t - \frac{1}{T} \sum_{t'=1}^T \mathbf{X}_{t'} \right) \left(\mathbf{X}_{t+\lambda} - \frac{1}{T} \sum_{t'=1}^T \mathbf{X}_{t'} \right) \right\rangle$$

$$= \frac{1}{T} \sum_{t=1}^{T-\lambda} \mathbf{X}_t \mathbf{X}_{t+\lambda} - \left(\frac{1}{T} \sum_{t=1}^T \mathbf{X}_t \right)^2$$

$$A_\lambda^{(1)} = \left\langle \left(X_t - \frac{1}{T} \sum_{t'=1}^T X_{t'} \right) \left(X_{t+\lambda} - \frac{1}{T} \sum_{t'=1}^T X_{t'} \right) \right\rangle$$

$$= \frac{1}{T} \sum_{t=1}^{T-\lambda} X_t X_{t+\lambda} - \left(\frac{1}{T} \sum_{t=1}^T X_t \right)^2$$

and

$$\begin{aligned}
A_{\lambda}^{(2)} &= \left\langle \left(X_t - \frac{1}{T-\lambda} \sum_{t'=1}^{T-\lambda} X_{t'} \right) \left(X_{t+\lambda} - \frac{1}{T-\lambda} \sum_{t'=1}^{T-\lambda} X_{t'+\lambda} \right) \right\rangle \\
&= \frac{1}{T-\lambda} \sum_{t=1}^{T-\lambda} X_t X_{t+\lambda} - \left(\frac{1}{T-\lambda} \sum_{t=1}^{T-\lambda} X_t \right) \left(\frac{1}{T-\lambda} \sum_{t=1}^{T-\lambda} X_{t+\lambda} \right) . \\
A_{\lambda}^{(2)} &= \left\langle \left(X_t - \frac{1}{T-\lambda} \sum_{t'=1}^{T-\lambda} X_{t'} \right) \left(X_{t+\lambda} - \frac{1}{T-\lambda} \sum_{t'=1}^{T-\lambda} X_{t'+\lambda} \right) \right\rangle \\
&= \frac{1}{T-\lambda} \sum_{t=1}^{T-\lambda} X_t X_{t+\lambda} - \left(\frac{1}{T-\lambda} \sum_{t=1}^{T-\lambda} X_t \right) \left(\frac{1}{T-\lambda} \sum_{t=1}^{T-\lambda} X_{t+\lambda} \right) .
\end{aligned}$$

Other definitions exist and differ in the prior estimate of μ and the normalization constant, i.e. $\frac{1}{T}$

$$\frac{1}{T} \text{ versus } \frac{1}{T-\lambda} \frac{1}{T-\lambda} .$$

I prefer the first one because it is simpler in terms of programming, so we will use it in the

following sections. Let us rewrite its expression by defining $\bar{X} = \frac{1}{T} \sum_{t=1}^T X_t = \frac{1}{T} \sum_{t=1}^T X_t$.

$$\begin{aligned}
A_{\lambda} &= A_{\lambda}^{(1)} = \frac{1}{T} \sum_{t=1}^{T-\tau} X_t X_{t+\lambda} - \bar{X}^2 \\
A_{\lambda} &= A_{\lambda}^{(1)} = \frac{1}{T} \sum_{t=1}^{T-\tau} X_t X_{t+\lambda} - \bar{X}^2
\end{aligned}$$

2.2 Fourier analysis

While the autocorrelation of a continuous-time time series can be easily derived with a **Fourier transform**, some special steps are, however, required before applying it on a discrete-time time series \mathbf{X} . To do so, let $\mathbf{Y} = \{Y_t \mid 1 \leq t \leq 2T\}^Y = \{Y_t \mid 1 \leq t \leq 2T\}$ be a time series with

$$\begin{aligned}
Y_t &= \begin{cases} X_t - \bar{X} & (1 \leq t \leq T) \\ 0 & (T < t \leq 2T) \end{cases} . \\
Y_t &= \begin{cases} X_t - \bar{X} & (1 \leq t \leq T) \\ 0 & (T < t \leq 2T) \end{cases} .
\end{aligned}$$

It is **padded with zeros** because \mathbf{X} is not a periodic signal required by a Fourier transform.

Then, we can compute another $2T$ -unit long time series $\mathbf{Z} = \{Z_t \mid 1 \leq t \leq 2T\}$

$\mathbf{Z} = \{Z_t \mid 1 \leq t \leq 2T\}$ with

$$Z = \frac{1}{T} \mathcal{F}^{-1} \left[|\mathcal{F}(Y)|^2 \right],$$

$$Z = \frac{1}{T} \mathcal{F}^{-1} \left[|\mathcal{F}(Y)|^2 \right],$$

where \mathcal{F} and \mathcal{F}^{-1} respectively denote Fourier transform and its inverse. [Remember that $\mathcal{F}(Y)$ is a complex object, so $|\mathcal{F}(Y)|^2$ refers to the product between $\mathcal{F}(Y)$ and its complex conjugate.] The autocorrelation of XX is finally given by

$$A_{\lambda}^{(3)} = Z_{\lambda+1} \quad \text{for } \lambda \in [0, T-1];$$

$$A_{\lambda}^{(3)} = Z_{\lambda+1} \quad \text{for } \lambda \in [0, T-1];$$

surprisingly, $A_{\lambda}^{(1)} \equiv A_{\lambda}^{(3)}$ without any numerical differences, and this implies $A_{\lambda}^{(1)}$ is more accurate than $A_{\lambda}^{(2)}$.

Technically speaking, \mathcal{F} and \mathcal{F}^{-1} are performed by the algorithm of **fast Fourier transform** (FFT). It can speed up the computation of autocorrelation from $O(T^2)$, which $A_{\lambda}^{(1)}$ gives, to $O(T \ln T)$. This is the greatest (and perhaps the only) advantage of using $A_{\lambda}^{(3)}$. If you do not understand how to program an FFT, you should always stick to $A_{\lambda}^{(1)}$ because—as the saying goes—"people's time is more expensive than computers' time".

2.3 Correlation time

Once we obtain AA , we can determine at least how far two data points (X_{t_1}, X_{t_2}) should be separated so that they can be regarded as statistically independent. The answer is related to its characteristic timescale, namely **correlation time** τ . If XX is a **Markov process**, we can estimate τ by fitting

$$A_{\lambda} \sim e^{-\lambda/\tau}.$$

$$A_{\lambda} \sim e^{-\lambda/\tau}.$$

A more sophisticated analysis may fit

$$A_{\lambda} \sim e^{-(\lambda/\alpha)^{\beta}}$$

$$A_{\lambda} \sim e^{-(\lambda/\alpha)^{\beta}}$$

to get $\tau = \frac{\alpha}{\beta} \Gamma\left(\frac{1}{\beta}\right)$ instead, but this practice is rare and does not seem to produce better results.

Integrated correlation time. If the autocorrelation is perfectly exponential, i.e. $A_\lambda = A_0 e^{-\lambda/\tau}$

$A_\lambda = A_0 e^{-\lambda/\tau}$, we may estimate $\tau \equiv \int_0^\infty e^{-\lambda/\tau} d\lambda \equiv \int_0^\infty e^{-\lambda/\tau} d\lambda$ by **numerically integrating**

$\frac{A_\lambda}{A_0} \frac{A_\lambda}{A_0}$. This alternative estimate may be called the "integrated correlation time". Some people

argue that this method is more accurate than fitting, but I doubt this personally.

2.4 Interpretation

Autocorrelation may be viewed as a measure of **self-similarity**. While $X_t X_t$ and $X_{t+\tau} X_{t+\tau}$ are on average $e^{-\tau/\tau} \approx 37\% e^{-\tau/\tau} \approx 37\%$ similar, the similarity between $X_t X_t$ and $X_{t+2\tau} X_{t+2\tau}$ drops to $e^{-2\tau/\tau} \approx 14\% e^{-2\tau/\tau} \approx 14\%$, which happens to be a sufficiently good threshold of statistical independence. Consequently, $X_{1+2\tau} X_{1+2\tau}$ is deemed to have "forgotten" $X_1 X_1$, so we may even assume that XX starts to "forget" its history and thus become stationary at $t = 2\tau^t = 2\tau$.

But of course, the arguments here may not be universally true because they rely on numerous assumptions on the underlying form of XX . You should modify them wisely if, for example, XX apparently does not look stationary after $t = 2\tau^t = 2\tau$ or the autocorrelation AA does not resemble any exponential decay at all.

3. Sample statistics

We have now extracted $n \equiv \lfloor T/\tau \rfloor n \equiv \lfloor T/\tau \rfloor$ independent data points $\{X_{2\tau}, X_{4\tau}, X_{6\tau}, \dots\}$

$\{X_{2\tau}, X_{4\tau}, X_{6\tau}, \dots\}$ from XX . Its sample mean $\hat{\mu}$ is then refined to become

$$\hat{\mu} = \frac{1}{n} \sum_{i=1}^n X_{2\tau i},$$

$$\hat{\mu} = \frac{1}{n} \sum_{i=1}^n X_{2\tau i},$$

whereas its sample variance $\hat{\sigma}^2$ accordingly reads

$$\hat{\sigma}^2 = \frac{1}{n-1} \sum_{i=1}^n (X_{2\tau i} - \hat{\mu})^2.$$

$$\hat{\sigma}^2 = \frac{1}{n-1} \sum_{i=1}^n (X_{2\tau i} - \hat{\mu})^2.$$

3.1 Standard error of mean

The standard error of the sample mean $\hat{\mu}$ is given by

$$\delta = \sqrt{\frac{1}{n} \hat{\sigma}^2}.$$

$$\delta = \sqrt{\frac{1}{n} \hat{\sigma}^2}.$$

If you somehow do not care about or bother to compute the sample variance $\hat{\sigma}^2$, you may alternatively compute δ with

$$\delta = \sqrt{\frac{1+2\tau}{T} \hat{\sigma}_0^2},$$

$$\delta = \sqrt{\frac{1+2\tau}{T} \hat{\sigma}_0^2},$$

where $\hat{\sigma}_0^2 = \frac{1}{T-1} \sum_{t=1}^T (X_t - \bar{X})^2$ is the sample variance suggested by the original unfiltered \mathbf{X} . While they should be identical in theory, they may differ considerably in reality.

3.2 Standard error of variance?

We would also like to know how much the sample variance $\hat{\sigma}^2$ differs from the population variance, but we can hardly write down a formula for its standard error because it is affected by the error of $\hat{\mu}$ via some tedious calculus. Instead, we can make our lives easier by measuring the error algorithmically with the **bootstrap method**.

1. Let $\mathbf{B} = \{X_{2\tau}, X_{4\tau}, X_{6\tau}, \dots\}$ be the n independent data points, then denote their sample variance by s_1 .
2. Draw $|\mathbf{B}| = n$ terms from \mathbf{B} **with replacement** and record the sample variance s_2 of these new terms.
3. Repeat step 2 as many times possible to gather many sample variances $\{s_1, s_2, s_3, \dots\}$.
4. After sufficient trials, the **sample standard deviation** of $\{s_1, s_2, s_3, \dots\}$ will converge to a value, and it is the standard error of $\hat{\sigma}^2$.

In fact, the method does not require statistically independent data, so you may replace

$$\mathbf{B} = \{X_{2\tau}, X_{4\tau}, X_{6\tau}, \dots\} \text{ with } \mathbf{B} = \{X_1, X_2, \dots, X_T\}$$

$B = \{X_1, X_2, \dots, X_T\}$ in step 1, but the expense is that $|B| = n|B| = n$ will increase to $|B| = T|B| = T$ in step 2 and thus slow down the algorithm.

If you want to better understand the principles of all the methods mentioned here, you may read Sections 3.3 and 3.4 of *Monte Carlo Methods in Statistical Physics* (Barkema and Newman, 1999). Although it is written in physicists' language, the sections explain some useful techniques for handling a stationary time series.
